Canadian Technical Report of Hydrography and Ocean Sciences

Technical reports contain scientific and technical information that contributes to existing knowledge but which is not normally appropriate for primary literature. The subject matter is related generally to programs and interests of the Ocean Science and Surveys (OSS) sector of the Department of Fisheries and Oceans.

Technical reports may be cited as full publications. The correct citation appears above the abstract of each report. Each report is abstracted in *Aquatic Sciences and Fisheries Abstracts* and indexed in the Department's annual index to scientific and technical publications.

Technical reports are produced regionally but are numbered nationally. Requests for individual reports will be filled by the issuing establishment listed on the front cover and title page. Out of stock reports will be supplied for a fee by commercial agents.

Regional and headquarters establishments of Ocean Science and Surveys ceased publication of their various report series as of December 1981. A complete listing of these publications is published in the *Canadian Journal of Fisheries and Aquatic Sciences*, Volume 39: Index to Publications 1982. The current series, which begins with report number 1, was initiated in January 1982.

Rapport technique canadien sur l'hydrographie et les sciences océaniques

Les rapports techniques contiennent des renseignements scientifiques et techniques qui constituent une contribution aux connaissances actuelles, mais qui ne sont pas normalement appropriés pour la publication dans un journal scientifique. Le sujet est généralement lié aux programmes et intérêts du service des Sciences et levés océaniques (SLO) du ministère des Pêches et des Océans.

Les rapports techniques peuvent être cités comme des publications complètes. Le titre exact paraît au-dessus du résumé de chaque rapport. Les rapports techniques sont résumés dans la revue *Résumés des sciences aquatiques et halieutiques*, et ils sont classés dans l'index annuel des publications scientifiques et techniques du Ministère.

Les rapports techniques sont produits à l'échelon régional, mais numérotés à l'échelon national. Les demandes de rapports seront satisfaites par l'établissement auteur dont le nom figure sur la couverture et la page du titre. Les rapports épuisés seront fournis contre rétribution par des agents commerciaux.

Les établissements des Sciences et levés océaniques dans les régions et à l'administration centrale ont cessé de publier leurs diverses séries de rapports en décembre 1981. Une liste complète de ces publications figure dans le volume 39, Index des publications 1982 du *Journal canadien des sciences halieutiques et aquatiques*. La série actuelle a commencé avec la publication du rapport numéro 1 en janvier 1982.

ABSTRACT

Wagemann, R., and D.C.G. Muir. 1984. Concentrations of heavy metals and organochlorines in marine mammals of northern waters: overview and evaluation. Can. Tech. Rep. Fish. Aquat. Sci. 1279: v + 97 p.

Published data on heavy metal and organochlorine concentrations in tissues of cetaceans and pinnipeds, mainly from northern waters, were compiled. The data were subjected to multiple comparison by Scheffé's method, and assessed for significant differences.

Most cetaceans had mercury concentrations (wet weight basis) of 0.02-1.6 µg/g in muscle tissue, 1-2 µg/g in renal tissue, and 3-20 µg/g in the liver. Of all cetaceans some dolphins, pilot whales, and short-finned pilot whales had the highest recorded mercury levels in their tissues. Systematic differences in mercury levels among different species of animals were not apparent.

Most mean mercury concentrations (89% of the compiled data) in the liver of seals were below 65 µg/g, and below 3.4 µg/g and 0.94 µg/g in renal and muscle tissue, respectively. Among seals there was no differentiation of mercury concentration according to species of animals, but age seemed to be one of the factors determining the level of mercury in tissues. A limited number of other metals data (Zn, Cu, Pb, Se) are also given and discussed.

Mean cadmium concentrations in renal tissue of whales 28-64 µg/g were higher than in the same tissue of most seals and porpoises. Cadmium concentrations in kidneys of striped dolphins (25 µg/g on average) were comparable to the concentrations in whales. In both cetaceans and seals cadmium was consistently higher in renal tissue than in hepatic tissue by a factor of 2-5.

Statistical comparison of total DDT (ΣDDT) concentrations in cetaceans revealed four distinct groups. Dolphins from the California coast had higher ΣDDT levels than dolphins from the Mediterranean coast of France or porpoises from the Bay of Fundy. The latter group had significantly higher ΣDDT than all other groups. PCB levels followed a similar trend, but only two groups (coast of France and all other data) could be discerned.

Levels of ΣDDT and PCB in narwhal blubber (Pond Inlet, N.W.T., Canada) averaged 3.51 and 10.09 µg/g, respectively, with males having significantly higher levels than females. Results were not correlated with length of the animals. The residue levels in narwhals could not be distinguished statistically from other organochlorine data for cetaceans from Greenland or the North Atlantic.

Comparison of concentrations of PCBs in pinnipeds (blubber) revealed four distinct groups. Seals from the Baltic and the North Sea coast of the Netherlands had significantly higher PCB levels than all other animals. Levels of PCBs in seals from Canadian waters were significantly lower than those from the Baltic except for harbour seals in the Bay of Fundy. Five distinct groups of pinnipeds could be delineated for ΣDDT residues, with sea lions from the California coast having the highest levels, and seals from the Canadian Arctic the lowest.

Key words: marine mammals; heavy metals; chlorinated hydrocarbons; PCB; DDT; literature reviews; northern waters; cetaceans; pinnipeds; mercury; cadmium.

RESUME

Wagemann, R., and D.C.G. Muir. 1984. Concentrations of heavy metals and organochlorines in marine mammals of northern waters: overview and evaluation. Can. Tech. Rep. Fish. Aquat. Sci. 1279: v + 97 p.

Un ensemble de données disponibles sur les concentrations de métaux lourds et d'agents organochlorés trouvées dans des tissus de cétacés et de pinnipèdes des eaux septentrionales ont été rassemblées et une étude comparée de ces données d'après la méthode de Scheffé a été entreprise.

La plupart des cétacés avaient des niveaux de mercure (poids humide) de 0.02 à 1.6 µg/g dans leur tissu musculaire, de 1 à 2 µg/g dans le tissu rénal, et de 3 à 20 µg/g dans le tissu hépatique. Les tissus de certains dauphins, ainsi que ceux des globicéphales noirs de l'Atlantique et de globicéphales à nageoires courtes, contenaient du mercure aux niveaux les plus élevés enregistrés à ce jour. Les différences de niveaux entre ces animaux ne peuvent être attribuées à leur appartenance à une espèce plutôt qu'à une autre.

La plupart des niveaux moyens de mercure (soit 89% des données) étaient inférieurs à 65 µg/g dans le tissu hépatique, à 3.4 µg/g dans les tissus rénaux et à 0.94 µg/g dans le tissu musculaire. En comparant les espèces de phoques une à une, on n'a trouvé aucune différence dans les niveaux de mercure de leurs tissus. Cependent, on a constaté que l'âge semblait être un des facteurs déterminants de la concentration de mercure. Les résultats d'analyses supplémentaires sur un certain nombre de métaux, tel que le Zn, le Cu, le Pb et le Se, sont aussi présentés dans cet article.

Les concentrations moyennes en cadmium des tissus rénaux de baleines variaient entre 28 et 64 µg/g. Cependant elles étaient plus élevées chez la plupart des phoques et des marsouins. Les concentrations en cadmium du foie du dauphin bleu (Stenella coeruleoalba) étaient comparables à celles des baleines (25 µg/g en moyenne). Chez les cétacés et les pinnipèdes étudiés, le degré de concentration en cadmium était systématiquement plus élevé dans le tissu rénal que dans le tissu hépatique, dans un rapport de 2 à 5.

La comparaison statistique des concentrations totales en DDT (ΣDDT) constatées dans le

pannicule des cétacés, a révélé l'existence de quatre groupes distincts. Le pannicule des dauphins provenant des côtes Californiennes contenaient des concentrations de ΣDDT plus élevées que celles provenant des dauphins des côtes méditerranéennes de France ou de la baie de Fundy tandis qu'un quatrième groupe hétérogène contenait les niveaux les plus faibles. Les concentrations de PCB suivant la même tendance, avec deux groupes distincts cependant (un provenant des côtes de France, l'autre du restant des données).

Les niveaux de ΣDDT et PCB dans le pannicule des narvals (Pond Inlet, T.N.-O.) atteignaient en moyenne 3.51 et 10.09 µg/g, respectivement, le niveau des mâles étant sensiblement plus élevé que celui des femelles. Les résultats n'indiquaient pas de correspondance entre la teneur en DDT et la longueur totale des animaux. On n'a trouvé aucune différence significative entre les niveaux d'agents organochlorés obtenus chez le narval et les niveaux obtenus chez les cétacés du Groenland ou de l'Atlantique Nord.

La comparaison des concentrations d'agents organochlorés entres les divers pinnipèdes (pannicule) a révélé que les phoques des côtes des Pays-Bas baignées par la mer du Nord ont une teneur en PCB nettement plus élevée que tous les autres animaux étudiés. Les niveaux de PCB des phoques habitant les eaux canadiennes étaient sensiblement moins élevés que ceux de la mer Baltique, sauf les phoques communs de la baie de Fundy. On a pu distinguer cinq groupes de pinnipèdes sur la base de leurs concentrations respectives en ΣDDT, les otaries de Californie ayant les concentrations les plus élevées et les phoques de l'Arctique, les concentrations les plus basses.

Mots-clés: mammifères marins; métaux lourds; carbohydrates chlorinés; BPC; DDT; recherches bibliographiques; eaux du nord; cétacés; pinnipèdes; mercure; cadmium.

INTRODUCTION

A large body of data on mercury and chlorinated aromatic hydrocarbons in pinnipeds has been published over the past ten years. Reviews and qualitative comparisons of residue levels in various pinniped species from different geographic locations have been made (Holden 1978a, 1975). There is nevertheless a need for further updating of the existing data base and review of the literature. The published data on pollutant burdens in tissues of cetaceans is less extensive than for pinnipeds. An asssessment of some of this data has been made (Gaskin 1982). We have attempted a systematic documentation of the data base for pinnipeds and cetaceans in northern waters (up to mid 1983) and compared, statistically, heavy metal and organochlorine concentrations in various tissues largely from northern waters. The objective was to provide a readily accessible overview of most existing heavy metals and organochlorine data for marine mammals from northern waters, and to assess these data for any significant differences or similarities from which conclusions about hot spots of pollution might be drawn. A multiple means comparison of the data using Scheffé's method (Scheffé 1959) has been employed in the hope of obtaining a better perspective on the degree of hazard to marine mammals in Canadian waters, as well as other areas, from continued accumulation of heavy metals and chlorinated aromatic hydrocarbons. A further reason for doing such an analysis was simply to avoid the tendency of attributing significance, through visual inspection of data plots, to differences where there might be none.

This method of analysis (Scheffé 1959) was chosen because it is applicable to unequal sample sizes which was the situation faced here and because it is the most conservative such test. It was assumed that the populations were normally distributed. However, departures from normality have been reported for fish (Giesy and Wiener 1977), and this is probably also true for some mammalian tissues. It was, of course, not possible to test the data post publication for normality. The postulated significance levels must therefore be viewed with this in mind.

We recognized the possibility that the available data was not of uniform quality. It is well known that at the trace level, measurements are subject to considerable interlaboratory variability (Morrison 1976; Holden 1981; Holden et al. 1983). Since the data base considered here spans more than a decade, during which time methodologies and instrumentation may have changed, variability in the quality of data would also be expected from this source. A meaningful assessment of the data in this regard was impossible, and the available data were simply taken at face value. Concentrations reported here are all expressed on a wet tissue basis.

RESULTS AND DISCUSSION

MERCURY IN CETACEANS

A reasonably large number of mercury concentrations in tissues of cetaceans from northern waters has been published to date (Table 1). We made a statistical comparison of the concentration means (wherever standard deviations were available) using the Scheffé multiple comparison method (see Appendix) on the various groups of animals. In a few instances where the range but not the standard deviation was given, we estimated the latter from the range in the usual way (Beyer 1966). Means derived from fewer than three samples were not used in the analysis. The results of this analysis are shown in Fig. 1, 2 and 3 for mercury in liver, muscle and kidney, respectively. The bars in these figures are not error bars in the usual sense; they only indicate the outcome of the Scheffé test. The means were compared in all cases at the $\alpha = 0.10$ level of significance. Wherever the bars overlap, the corresponding means do not differ significantly, and only those groups differ significantly from each other whose bars do not overlap.

The average mercury concentrations in the liver of cetaceans (i.e. not individuals) ranged from 3-205 µg/g, but only the short-finned pilot whales, and striped dolphins (not shown in Fig. 1, off scale) having the highest mercury concentration, differed significantly from all other groups which did not differ amongst themselves despite the wide range of their means (3-20 µg/g) (Fig. 1). There is no distinct segregation (at $\alpha = 0.10$) between porpoises, narwhals and belugas, for example, as far as mercury in liver is concerned. Since most of the data in this order are for harbour porpoises from the east coast of the U.S.A. (ME) and Canada (N.S.), a global, regional comparison of Hg-levels was not possible. However, one harbour porpoise from the North Sea (index no. 32, Table 1) had a mercury level in the liver comparable to the highest levels in porpoises from the Atlantic coast in North America. Mercury levels in the liver of cetaceans and seals apparently are determined to a large extent by the age of the animal (Gaskin et al. 1979; Sergeant 1980), but this did not become overly apparent from the available data base. The fact that most groups consisted of only a few individuals also tended to make the analysis less discriminating.

There is undoubtedly a limit to the concentration of mercury (or any toxic metal) that an animal can tolerate in its tissues notwithstanding the beneficial effect that selenium may exert in this regard. For mercury in mammalian hepatic tissues this limit appears to be within the range of 100-400 µg/g, wet weight, (MARC 1980). Dead or ill seals and sea lions found in the wild with mercury levels in their livers within this range (Reijnders 1980; van de Ven et al. 1979; Buhler and Mate 1973; Henriksson and Karppanen 1969) would seem to be a manifestation of these critical limits. The mean concentration in the liver of the 1979-group of narwhals (index no. 13, Table 1) is approximately 6 µg/g, and the highest concentration in any individual of this group was 13 µg/g. Some short finned pilot whales have 100-360 µg/g of mercury (index no. 6, 15, 16, Table 1) and a group of striped dolphins from the east coast of Japan had up to 485 µg/g (205 µg/g on average, index no. 98, Table 1), a seemingly critically high concentration of mercury in liver.

Mercury levels in muscle tissue of cetaceans were segregated by Scheffé's procedure into three distinct groups (Fig. 2). The blue-white and striped dolphins (index no. 48, 98, Table 1) having the highest mercury concentration (6.73 and 7.02 µg/g, not shown in Fig. 2) were significantly different from all other groups. Most groups had mercury levels in muscle tissue in the range of 0.02-1.6 µg/g (Fig. 2). Pilot whales (index no. 8, 6, Table 1), with the second highest concentration (4 µg/g) are significantly different from dolphins and all other groups which do not differ significantly among themselves in their mercury levels (Fig. 2). It is noteworthy that baleen whales (sei, fin, minke) have the lowest concentration of mercury in their tissues. This may be a consequence of their diet as has been pointed out by Sergeant and Armstrong (1973), and a possible source of variable mercury levels among certain seal species. For cetaceans the available data are too few to show that neither location of catch nor species differences correlated with concentration of Hg in any tissues.

Mercury in renal tissue of cetaceans is highest (8.65 µg/g, Fig. 3) for short-finned pilot whales and striped dolphins (8.71 µg/g, not shown in Fig. 3, index no. 6, 98, Table 1) and next highest (3.56 µg/g) for some harbour porpoises from the coast of New Brunswick, Canada (index no. 27, Table 1). These groups differ significantly from each other and from all other groups (Fig. 3). Aside from these groups, cetaceans have mercury concentrations in renal tissue in the range of 1-2 µg/g. Quite consistently the pilot whales, short-finned pilot whales, and dolphins have the highest mercury levels in liver, muscle and kidney. The available data are not extensive enough to discriminate between various localities.

Hepatic tissue of cetaceans has consistently higher mercury levels than muscle or renal tissue by approximately a factor of five, while renal and muscle tissues have comparable mercury levels.

OTHER METALS IN CETACEANS

Concentrations of Zn, Cu, and Pb in cetaceans have been measured to date only in narwhals, harbour porpoises and the striped dolphin as far as we know (Table 2), but these data are insufficient for an extensive group-comparison by the Scheffé method. Concentrations of Cd and Se have been determined also in other cetaceans (Tables 2 and 3). The 1979-sample of narwhals has, of all the marine mammals recorded here, the highest average cadmium concentration in renal tissue (63.5 µg/g, Table 3) except one seal which had a slightly higher concentration (65.9 µg/g, index no. 126, Table 9). These narwhals were all caught in the same general area near Pond Inlet on Baffin Island. The 1979-group of narwhals do not differ significantly from the 1977 group of narwhals at 30.5 µg/g of Cd in their renal tissue (index no. 12, Table 3) at the $\alpha = 0.10$ level of significance, mainly because the concentration of cadmium in the tissues of narwhal varied more greatly from animal to animal than for any other metal. The only other whales in which cadmium concentrations have been measured are the short-finned pilot whale and the minke whale (a single animal in each case) with 42 µg/g and 28 µg/g of cadmium in their renal tissues, respectively (Table 3). Striped dolphins from the eastern coast of Japan (index no. 98) had similarly high cadmium concentrations in renal tissue (25 µg/g, average), apparently a consequence of the very high cadmium concentration in the squid which these dolphins ate (Honda et al. 1983). Why cadmium levels in renal tissue of whales should be as high as they are is an open question. It is known that the half-life of cadmium in the mammalian kidney varies greatly with species (e.g. three years for mice and ten years for man; Matsubara-Khan 1974; MARC 1980). Possibly the half-life of cadmium in whales is extremely long, which would mean that these animals are essentially incapable of eliminating this metal. Consistently the concentration of cadmium is higher in the kidney than in the liver by a factor of 2-4.

Selenium concentrations do not differ significantly among narwhals in any of the tissues examined (index no. 12, 13, Table 4). Some concentrations of Se in the liver are available for short-finned pilot whales (index no. 15, 16, Table 4), and these are significantly higher than in narwhals. As noted before, these animals also have much higher mercury concentrations in their tissues than narwhals.

The 1979-narwhal data had been subjected to regression analysis (Wagemann et al. 1983), which revealed that the length of narwhals correlated positively very strongly with the mercury concentration in kidney, muscle and blubber, and with cadmium also positively (although somewhat less strongly) in muscle and kidney. The correlations between length and the concentration of other metals were generally negative for at least one sex, which would imply (to the extent that length of an animal and its age are related) that concentrations of Cu, Zn, and Pb are diminishing with time in the respective tissues, while Hg is accumulating in kidney, muscle, and blubber, and Cd is accumulating in kidney and muscle.

Mercury correlated strongly, positively with selenium in liver and kidney, and in liver also with cadmium. Zinc correlated positively with cadmium in the liver and kidney (Wagemann et al. 1983). Which particular metals are associated with each other clearly depends on the type of tissue; however one pair of elements namely, mercury and selenium, consistently correlated positively in liver and kidney. This is an interesting association since the latter element is reported to have an ameliorating influence on the toxicity of mercury in fish (Ganther et al. 1972), and also appears to govern the accumulation and affect the toxicity of mercury in mammalian tissues (Parizek et al. 1971; El Bergearmi et al. 1973; Potter and Matrone 1974; Chen et al. 1975; Hansen and Kristensen 1979). The atomic concentration ratio Hg/Se is claimed to be most frequently near 1, for hepatic tissue. This ratio has been reported to range from 1-9 for hepatic tissue in seals (Koeman et al. 1975, 1973). In narwhals (1979-group), this ratio was found to be in the range of: 0.22-1.70 for liver, 0.066-0.56 for renal tissue, 0.039-

1.37 for blubber, and 0.23-1.37 for muscle (Wagemann et al. 1983). The average atomic ratio (Hg/Se) was: 0.59 for liver, 0.21 for kidney, 0.15 for blubber and, 0.75 for muscle, of the 1979-group of narwhals.

MERCURY IN PINNIPEDS

We have compiled most published data on concentrations of mercury in various tissues of pinnipeds from northern waters (Table 5) with the notable exception of any data for the palaearctic region, which are not readily available. The outcomes of the multiple comparison by Scheffé's procedure are shown in Fig. 4, 5, 6, for liver, muscle and kidney respectively. Comparisons were also made of mercury in blubber and other metals in various tissues but these are not shown since the data were not plentiful. Although this work deals largely with animals from northern waters, some harbour seals from the California coast, U.S.A. were included for purposes of reference (index no. 179, Table 5). California harbour seals with 269 µg/g of mercury in the liver had nearly as high a concentration as harbour seals from the Dutch coast (293 µg/g). These concentrations while significantly higher than the average concentration in hepatic tissue of most groups of seals (Fig. 4), are not significantly higher than the average concentration of 230 µg/g and 138 µg/g in ringed seals from the Baltic area (index no. 110, 101, Table 5), or the average concentration of 143 µg/g in some bearded seals (index no. 236, Table 5) from Victoria Island, E. Arctic, Canada. No single species appears to be significantly different from all other species in mercury concentration in the liver. Only the few groups of animals with the highest concentrations irrespective of species were significantly different from some groups with the lowest concentration (Fig. 4), and this was seemingly more a consequence of age differences than species differences. One notable result of the analysis is the lack of differentiation among species. Although we did not make a detailed analysis of the influence of age on mercury concentration in the liver, other workers have found a correlation between mercury concentrations in seals and their age (Sergeant 1980; Smith and Armstrong 1978; Drescher et al. 1977; Heppleston and French 1973). The influence of age on concentration does become somewhat apparent in Fig. 4, where the lowest concentration range (0.23-10 µg/g) is comprised only of young seals (i.e. less than 6 years old) and the highest concentration range (90-270 µg/g) is seemingly comprised only of animals that are older than 7 years. The intermediate concentration range (10-90 µg/g) includes animals of all ages. Although harp seals have some of the lowest mercury concentrations in the liver, some ringed seals have similarly low concentrations (Fig. 4). The lack of differentiation among the various groups generally, must to some extent also be the result of small sample sizes from which the means were derived.

Although visual observation of Fig. 4, 5, and 6 reveals no striking correspondences between mercury concentrations in liver and muscle or liver and kidney, such correspondences do exist. When the average mercury concentrations in the liver were linearly regressed on the average mercury concentrations in muscle or renal tissues (of the same group) the correlation coefficients were in each case significant at $\alpha = 0.05$. Still better fits were obtained with curvilinear regression, of the type $y = ae^{bx}$ where x is the mercury concentration in the liver and y is the mercury concentration in either muscle or renal tissue. The following constants were obtained (dry-wt. basis): for muscle-liver, $a = 0.2765$, $b = 0.0187$; for kidney-liver, $a = 1.471$, $b = 0.0130$.

In the absence of a sufficiently large and good data base any answer to the question of what is a normal or conversely an abnormally high concentration of heavy metals in tissues of seals can only be tentative. The great majority of seals (89% of all such averages) have mercury concentrations in the liver less than 65 µg/g (Fig. 4). If infrequency of occurrence of a datum can be taken as an indication of its abnormality, then mercury levels in the liver of seals in excess of 65 µg/g could be considered as lying outside the normal range irrespective of the age of the animal. The corresponding limits in muscle and kidney tissue when calculated from the above-mentioned regression equations using 65 µg/g for liver, are 0.94 µg/g and 3.4 µg/g, respectively. Concentrations greater than these values could therefore, by the same criterion, be considered as being abnormally high for these tissues irrespective of age.

Ringed seals from the Baltic area have, at 82 µg/g of Hg in muscle (index no. 101, Table 5) the highest concentration recorded here for muscle and this is significantly higher than the concentration in any other group (Fig. 5). The second and third highest mean concentration at 3.5 µg/g, and 2.5 µg/g in muscle (index no. 110, 116, Table 5) also for ringed seals from the Baltic are significantly higher than in most other groups (Fig. 5). Unfortunately, muscle concentrations were not reported for the seals from the Dutch Wadden Sea (index no. 324C, 324D) which had very high concentrations of mercury in their livers. Probably these seals also had high concentrations of mercury in muscle tissue. Two groups of seals which were among those with the lowest concentrations (index no. 237, 108, Fig. 5) had significantly lower concentrations than some other groups. The remaining groups which make up the majority of data in Fig. 5, and which span the concentration range (in terms of means) from 0.1-1.4 µg/g in muscle, did not differ significantly among themselves. Only 24% of all groups in Fig. 5, have concentration means higher than 0.94 µg/g.

In seal renal tissue, the highest mean concentrations of mercury were 17.0, 7.5 and 7.4 µg/g (index no. 324D, 324C, 110, Table 5), and these were significantly higher than in groups with the lowest concentration (0.14-2.6 µg/g, Fig. 6). The remaining groups span the range from 2.4-5.2 µg/g without differing significantly among themselves, nor do they differ from the highest concentrations. As expected, the groups with the highest concentration of mercury in renal tissue were the same as those that had very high concentrations of mercury in muscle and liver.

OTHER METALS IN PINNIPEDS

The mean concentration of zinc in the liver of all seals ranged from 34-81 µg/g. The highest concentration differed significantly from all others except the second and third highest namely, 59 and 57 µg/g (index no. 203, 205, Table 6). All remaining groups had concentration means in the range from 34-56 µg/g, and these did not differ significantly among themselves. The highest zinc concentration in liver was 109 µg/g in a Weddell seal from the Antarctic (index no. 249). As would be expected, the same animal had also a high concentration of zinc in muscle (84 µg/g). The mean concentrations of zinc in muscle tissue ranged from 20-34 µg/g (index no. 127, 208, Table 6), and in renal tissue from 19-46 µg/g (index no. 198, 128, Table 6). Concentrations of some individuals (rather than group means) do fall outside this range. No group differs from any other significantly in concentration neither in muscle nor in kidney.

A single leopard seal fetus from the Antarctic (index no 148) had at 53 µg/g copper in the liver the highest concentration. A group of leopard seals of unknown age (but probably young) from the Antarctic (index no. 246, Table 7) had nearly as high a concentration of copper in the liver (44.6 µg/g). Some grey seals from the North Sea (index no. 163, Table 7) had the third highest concentration (28 µg/g). Only these two groups differed significantly from other groups. All other groups had copper concentrations in the liver in the range of 5.7-15 µg/g, and these did not differ among themselves. Young animals seem to have higher concentrations than old ones, Table 7. Only four concentration means of copper in muscle and kidney were available for comparison. These range from 0.65-3.2 µg/g in muscle, and 2.5-10.6 µg/g in the kidney. In the latter organ only the highest mean (index no. 129, Table 7) was significantly different from others, and in muscle the highest and lowest means were each different from the rest.

In the liver the majority of lead concentration means were in the range of 0.15-0.60 µg/g (Table 8) with no significant differences among groups within that range regardless of species. The three highest concentration means (2.3, 5, 10 µg/g, Table 8) were each significantly different from all other means. For muscle only three lead concentration means were available two of which (0.04, 1.2 µg/g; Table 8) differed significantly from each other. In kidney tissue the concentrations (means) ranged from 0.32-1.17 µg/g (Table 8) with some significant differences occurring among groups, but the total number of groups available for comparison was only five.

Some ringed seals from Greenland (index no. 130, Table 9) with a mean of 17.0 µg/g of cadmium in the liver had a significantly higher concentrations than any other group. All other groups had mean concentrations of cadmium in the liver in the range of 0.018-7.32 µg/g (Table 9), and none of them differed significantly among themselves. In muscle tissue the cadmium mean concentrations span the range from 0.029-0.15 µg/g (Table 9), but only the highest mean differed from some others. In renal tissue, despite the wide range of cadmium concentrations (0.10-37.4 µg/g, Table 9) there was no significant difference between any of the means. This seems to be again mainly a consequence of the large variation in cadmium levels among individual animals (large standard deviations), seemingly peculiar to this metal. The cadmium concentration is consistently higher, by a factor of 2 to 5, in renal tissue than in hepatic tissue. It appears that on the whole cadmium in renal and hepatic tissues of seals is lower than in the corresponding tissues of some whales.

Only one concentration mean of selenium in muscle tissue (0.57 µg/g, Table 10) was reported in the literature (index no. 246). In the liver all but three groups have concentration means in the range of 1.80-36.0 µg/g (Table 10), and these groups do not differ significantly among themselves. A group of ringed seals from the Baltic area (index no. 110, Table 10) at 81 µg/g, and two other groups of harbour seals from the Danish and Dutch coasts (index no. 324C, 324D), at 112 and 109 µg/g respectively, had the highest selenium concentration in the liver, and these were significantly higher than the means of most other groups. As pointed out previously, these same groups of seals also had the highest levels of mercury.

CHLORINATED HYDROCARBONS IN CETACEANS

There are a growing number of reports in the literature on levels of polychlorinated biphenyls (PCBs), 1,1-bis(4-chlorophenyl)-2,2,2-trichloro-ethane (DDT) and its dechlorinated metabolites (ΣDDT) and other organochlorine pesticide residues in cetaceans. Gaskin (1982) has reviewed many of these reports and compared levels of these contaminants in animals from different geographical areas. Tables 11 and 12 list published results for PCBs and ΣDDT where two or more specimens were reported and includes results from the analysis of narwhal blubber samples from our laboratory (index No. 13A and 13B). Statistical comparisons of the mean concentrations of PCBs and ΣDDT in cetacean blubber were made using Scheffé's test (at the α=0.10 level of significance) for all results consisting of 5 or more animals. In some cases results of male and female specimens which were reported separately by the authors (e.g. index no. 59, 60, 54, 55, Tables 11 and 12) were pooled to increase the size of the group and hence the sensitivity of the comparison.

Cetaceans are differentiated into four distinct groups on the basis of ΣDDT levels in blubber using Scheffé's test (Fig. 7). Dolphins from the coast of California (1968-76) have the highest levels of ΣDDT reported for cetaceans (index no. 85, 87), significantly higher than all other reports. Dolphins from the coast of France (index no. 79) and porpoises from the Bay of Fundy (sampled in 1969-70) had significantly higher ΣDDT levels than all remaining specimens (Fig. 7) which included baleen whales and all Arctic species. Fewer results were available for comparision of PCB than DDT concentrations by use of Scheffé's test but a similar trend was

evident (Fig. 8) although only two distinct groups are apparent. Dolphins from the coast of France (index no. 79) had significantly higher PCB levels than cetaceans from Greenland and from several locations in the North Pacific ocean. Two bottlenose dolphin specimens not included in the statistical comparison (index no. 85) had PCB levels averaging 435 µg/g in blubber which are among the highest reported levels for this contaminant in cetaceans. Levels of PCBs (but not ΣDDT) in porpoises from the North Sea (index no. 76, 23) and the Bay of Fundy were relatively high (79-114 µg/g blubber) but could not be distinguished statistically from all other results. The high levels of PCBs and DDT in dolphins reported by Alzieu and Duguy (1979) pertain primarily to animals from the Mediterranean coast of France. These authors observed mean concentrations of 47.7 µg/g PCBs in dolphin (Stenella caeruleoalba) fat (lyophilized) from the Atlantic coast (one specimen) and 122-259 µg/g in the same species from the Mediterranean. The results in Fig. 7 and 8 are from a combined sample reported by the authors (index no. 78, 79, 80, Tables 11 and 12).

The results of PCB and ΣDDT residues in cetaceans, although fewer than reports on the same contaminants in pinnipeds, provide interesting information on the geographic distribution of these residues (Gaskin 1982). ΣDDT levels were extremely high in cetaceans from the coast of California and Bay of Fundy sampled in the late 1960's and early 1970's presumably reflecting large scale agricultural and forestry uses as well as manufacturing (in California). Both ΣDDT and PCB levels are high in cetaceans from the French coast while animals from the North Sea (The Netherlands coast and the U.K.; in blubber, index no. 86, 23, 51) had 2-fold higher PCB than ΣDDT levels. Narwhals from the Baffin Island area also have about 2-fold greater PCB than ΣDDT levels (index no. 13). Belugas in the Mackenzie River Delta had similar ΣDDT levels in blubber to those in the Eastern Arctic but far lower PCB levels (i.e. a detection limit of 0.5 µg/g was not exceeded, Addison and Brodie (1973)) (index no. 54) indicating that food chain contamination by PCBs is much greater in the North Atlantic than in the Beaufort Sea. Cetaceans in Japanese waters had similar PCB and ΣDDT levels and could not be distinguished statistically from Arctic-dwelling species (Fig. 7 and 8).

Levels of PCBs and ΣDDT in baleen whales (index no. 14, 57, 58A, 59, 60, 67, Tables 11 and 12) are lower than those of other species inhabiting roughly the same geographic location. This reflects the diet of Balaenoptera which consists primarily of crustaceans. Euphausiid, squid and fish-eating cetaceans can be roughly ranked according to increasing chlorinated hydrocarbon levels corresponding to their positions on the food chain (Gaskin 1982).

Comparison of ΣDDT levels in animals sampled over a 5-10 year period may not reflect decreasing levels of this contaminant following banning of this insecticide in the early 1970's. Decreases in ΣDDT concentrations in blubber over a five year period from the late 1960's to the mid-1970's have been observed in seals from the Farne Islands (Holden 1978b), but no significant decrease in ΣDDT levels in porpoises sampled in the Bay of Fundy between 1968 and 1977 has been observed. In fact mean levels actually increased slightly between 1975 and 1977 (Gaskin 1982). Unfortunately there are, as of this writing, no other reports of continuous monitoring of cetacean populations for chlorinated hydrocarbons. Given the continued use of DDT in many developing countries, and its persistence in the environment it appears valid to compare ΣDDT levels of various populations without taking into account the date of sampling.

PCB and ΣDDT concentrations in liver, kidney and muscle of cetaceans are also reported in Table 11 and 12 but there were insufficient numbers to make statistical comparison worthwhile. The importance of blubber as an indicator tissue in cetaceans is illustrated by Tanabe et al. (1981) who determined whole body burdens of PCB, ΣDDT, HCB and hexachlorocyclohexane isomers (HCH) in 5 striped dolphins ranging in age from 3 mo. to 36.5 yr. Greater than 93% of the chlorinated hydrocarbon residues were present in blubber regardless of age or sex. Muscle contained <7% of the residues although it comprised 55% of body weight while all other tissues contained <1% of the body burden.

Correlation of ΣDDT and PCB levels with age of pinnipeds has been frequently attempted but few correlations have been made with cetaceans because of lack of age data. Gaskin et al. (1983) reported a significant positive correlation of PCB levels in male harbour porpoise blubber with age. A negative correlation (not significant at $P \approx 0.01$) of age with PCB levels in female blubber was observed. Taruski et al. (1975) found higher organochlorine levels in "mature" compared to "immature" animals. Gaskin et al. (1971) reported lower levels of ΣDDT in suckling male porpoises than mature males. However, pregnant and lactating females had significantly lower concentrations of ΣDDT in blubber and liver than males or immature females. Concentrations of ΣDDT and PCB in narwhal blubber (index no. 13A, 13B) were not correlated with length of the animals, but stepwise regression analysis of log ΣDDT and log PCB concentrations on sex (0 = males; 1 = females) and length (cm) indicated correlations with gender ($r=-0.65$ and -0.54 for log ΣDDT and log PCB respectively). Correlations were not improved using the cross-product (sex)x(length). ΣDDT concentrations could be expressed by the regression equation log ΣDDT=-0.606(sex) + 0.647 ($R^2=0.42$) while PCB concentrations could be expressed as log PCB = -0.247(sex) + 1.054 ($R^2=0.30$). Gaskin et al. (1983) reported a significant correlation of PCB levels in porpoise blubber with length for males only. Body size is unlikely to correlate well with organochlorine concentration except perhaps in young animals because it increases asymptotically with time, however, it is frequently the only data for cetaceans. Higher ΣDDT and PCB levels are generally observed in male than in female cetaceans and this difference has been thoroughly documented in pinnipeds (Helle et al. 1976b). The differences in organochlorine concentrations with sex are readily explained by excretion of these compounds via lactation, as demonstrated in seals (Addison and Brodie 1977).

Other chlorinated hydrocarbon residues frequently reported in cetaceans include HCB, HCH isomers, chlordane, oxychlordane, trans-nonachlor, dieldrin and o,p-DDT isomers. In general, these compounds are present at levels 100 to 1000-fold lower than PCB or ΣDDT making assessment of their effects difficult.Recent reports of relatively high toxaphene and chlordane residues (10 - 11 µg/g blubber) in grey seals from the Baltic Sea (Jansson et al. 1979) and chlordane in Canadian polar bears (Norstrom, Canadian Wildlife Service, Ottawa, personal communication) suggest that these pesticides may be increasing in concentration in wildlife. O'Shea et al. (1980) reported toxaphene residues averaging 0.13 µg/g in dolphins and porpoises from California and Japan.

There is little information on what concentrations of PCB or ΣDDT in cetaceans may present a health risk to the animals or may lead to reproductive failure (Holden 1978a; Gaskin 1982). Alzieu and Duguy (1979) have suggested on the basis of dolphin results that concentrations of PCBs in liver of 20 mg/kg (lyophilized tissue) may present a health risk to the animals. This would correspond to a level of 50 - 200 µg/g (wet weight) in blubber based on their results. Concentrations of PCBs in ringed seals in the 50-100 µg/g range have been linked to the low reproductive rate of grey, harbour and ringed seals in the Baltic (Helle et al. 1976a; Jensen et al. 1979). Premature parturition in California sea lions has been linked to ΣDDT levels in the 626-1039 µg/g range and PCB levels in the 85-145 µg/g range (DeLong et al. 1973). Porpoises in the North Sea (index no. 76, 23), the Mediterranean coast of France (index no. 79), the Bay of Fundy (index no. 92A) and the California coast have PCB levels in the 50-200 µg/g range which may put these populations at risk.

CHLORINATED HYDROCARBONS IN PINNIPEDS

A large body of literature exists on concentrations of chlorinated hydrocarbons in pinnipeds. Holden (1972, 1975, 1978a) has reviewed the literature and compared results reported for pinnipeds in various geographical areas. Tables 13 and 14 list most of the published reports of ΣDDT and PCBs, respectively, for pinnipeds in northern waters up to mid 1983. Reports on single animals and those in southerly waters were omitted. Mean concentrations of ΣDDT and PCBs in blubber were compared at the α=0.10 level of significance, by use of Scheffé's test as described for cetaceans. Means derived from fewer than seven animals were omitted in order to improve the comparison. Exceptionally high PCB levels in five harbour seals from the North Sea (index no. 288) were included in the PCB comparison and in several cases results from the same species in the same locale, that were reported separately by the authors (eg. adult males and females) were pooled to increase sample size (index no. 106, 310, 214, 216).

Five distinct groups could be delineated by Scheffé's test on ΣDDT levels in pinniped blubber (Fig. 9). Sea lions from the California coast, sampled in the early 1970's, had significantly higher ΣDDT levels than all other pinnipeds (index no. 325, 326A). Two groups of seals from the Baltic Sea and Gulf of Bothnia (index no. 281, 280, 252) had significantly higher ΣDDT than all pinnipeds except California sea lions. Harbour seals from the North Sea (index no. 212, 296) had ΣDDT levels that were not significantly different from those of harp, grey and ringed seals in the Gulf of St. Lawrence (index no. 313, 310, 226), Sable island (index no. 282, 283), Greenland (index no. 106, 214, 322) or Scotland (index no. 212, 296, 286A). A fifth group consisted of female ringed seals from the Baltic area (index no. 251, 253-255) and harbour seals from the Gulf of Maine (index no. 165) which differed significantly from the high and low groups with ΣDDT concentrations in the 50-110 µg/g range (Fig. 9).

Average PCB concentrations in pinniped blubber that were compared statistically ranged from 0.96-1470 µg/g (generally reported on a wet weight basis) (Fig. 10). Four distinct groups emerge from the statistical comparison. Harbour seals from the North Sea coast of the Netherlands and Germany sampled in 1970-71 (index no. 288) and again in 1975-76 (index no. 324B) had the highest average PCB levels reported for any marine mammals. The 1970-71 samples were significantly higher than all other results while the 1975-76 results could not be distinguished statistically from grey, harbour, and ringed seals from the Baltic (index no. 252-255). One factor not taken into account in the statistical comparison was the date of sample collection. Most samples used in the comparison were collected between 1968 and 1977. Use of DDT was curtailed in Europe and North America by the early 1970's. Consistent decreases in ΣDDT levels in blubber (from 20 µg/g to 6 µg/g) have been noted in grey seals from the Farne Islands sampled between 1968 and 1975 (Holden 1978b). Harp seals from the Gulf of St. Lawrence sampled in 1973 were found to have lower levels of ΣDDT and PCB than those sampled in 1971 (Jones et al. 1976). Other reports suggest that PCB levels in seals did not decrease during the 1970's. Holden (1978b) reported virtually identical PCB levels in grey seals from the Farne Islands between 1968 and 1975. Sergeant (1980) reported PCB levels in harp seals (index no. 324, Table 14) sampled in 1979 that were very similar to those reported by Addison et al. (1973) for samples collected in 1971 (index no. 310, 311).

As noted with organochlorine residues in cetaceans, the PCB and ΣDDT residues in pinnipeds can provide information on the geographic distribution of these contaminants. Sea lions from the California coast (sampled in 1970) had extraordinarily high ΣDDT levels (index no. 325, 326A) but they had PCB levels that were about 10-fold lower and similar to those in seals from the Baltic Sea (Fig. 10). The high ΣDDT levels in sea lions and dolphins from the California coast reflect high contamination with DDT in this region. PCB levels were up to 4-fold higher in dolphins than in sea lions. Harbour seals from the North Sea coast of the Netherlands had high PCB levels but their ΣDDT concentrations could not be distinguished statistically from ringed and grey seals in the Baltic or

harbour seals from the Bay of Fundy (Fig. 9). ΣDDT levels were also higher than PCB in seals from the Gulf of Bothnia and Bothnian Bay (index no. 215-255). Pinnipeds in the Canadian Arctic and Greenland had PCB and ΣDDT levels generally less than 10 µg/g in blubber (Fig. 9 and 10) which suggests these contaminants are widely dispersed, but no consistent trends in PCB/ΣDDT ratios were apparent. Seals and walrus from Greenland had 4 to 7-fold greater PCB levels than ΣDDT (Clausen 1978; Born et al. 1981) as did ringed seals from Holman Island (Addison and Smith 1974). However, other seal samples from the Canadian Arctic and Greenland (mainly ringed seals, index. no. 256, 257, 106, 107) had similar or slightly higher (up to 2-fold) levels of ΣDDT than PCB (Bowes and Jonkel 1975; Johansen et al. 1980).

The age range of the animals is included in Fig. 9 and 10, as stated by the authors, since there have been several reports correlating age of male pinnipeds with organochlorine residue levels (Addison and Smith 1974; Helle et al. 1976b; Born et al. 1981). Mature males generally have the highest organochlorine levels within a pinniped population. Female pinnipeds have generally lower PCB and ΣDDT levels presumably due to mobilization and excretion of organochlorines during lactation and their residue levels do not correlate with age. Parturition is not thought to be a major pathway of loss of organochlorines since the foetus in both pinnipeds and cetaceans contains less than 1% of the residue present in maternal blubber (Donkin et al. 1981; Tanabe et al. 1981). Addison and Brodie (1977) demonstrated that during lactation, grey seals may excrete an amount of ΣDDT and PCBs similar to that which they would likely ingest from a fish diet.

Other organochlorine residues frequently reported in pinniped tissues include HCB, HCH isomers and dieldrin. Like the DDT residues, dieldrin has been found to be decreasing in blubber of grey seals from Scotland sampled between 1965 and 1974 (Holden 1978a). Improvements in analysis of chlorinated hydrocarbons by use of capilliary columns and gas chromatography-mass spectrometry have brought about identification of other chlorinated compounds including chlordane isomers (Kerkhoff and De Boer 1982), mirex (Ten Noever de Brauw et al. 1973), toxaphene (Jansson et al. 1979) and polychlorinated terphenyls (PCT) (Renberg et al. 1978). Toxaphene and Σchlordane residues in Baltic grey seal blubber were similar (10-11 µg/g) but were only 1-2% of the DDT and PCB levels in the same sample. PCT levels in blubber of three Baltic grey seals ranged from 0.5-1.0 µg/g or 0.5-1.4% of PCB levels. The high PCB levels in seal blubber have led to attempts to identify polychlorinated dibenzofurans (PCDFs) which are contaminants in PCB fluids and are formed during pyrolysis or incomplete combustion of PCBs (Bowes et al. 1973; Rappe and Buser 1980). Rappe et al. (1981) confirmed the presence of a series of PCDFs totalling 40 pg/g in Baltic grey seal blubber. The major components identified were penta- and hepta- CDFs as well as the toxic 2,3,7,8-CDF isomer (1 pg/g). The PCDF components were present at about 2.5×10^6 - fold less than PCB levels in the blubber. Individual PCB isomers have generally not been monitored in pinniped blubber to date and authors have reported residues based on comparison with commercial formulations such as Arochlor 1254/1260 or Phenochlor DP-6. Donkin et al. (1981) used a microwave plasma detector to monitor chlorinated hydrocarbons in seal tissues and identified PCB isomers based on Cl/C ratios. They reported that hexa- and heptachlorobiphenyls were the major PCB isomers present (actual congeners were not identified) representing about 87% of total PCB residues in grey seal blubber. Donkin et al. (1981) also determined total organohalogens in seal blubber extracts by microcoulometry and found that total residue measured by GLC (as PCB, ΣDDT and dieldrin) averaged 66.9% of that the organo-halogens present. A major portion of the remaining organochlorine residue in blubber was likely in the form of metabolites of PCBs and DDT. Jensen and Jansson (1976) reported that methylsulfone metabolites of PCB and DDE were present at about 20 µg/g in the Baltic seal blubber which contained 150 µg/g PCB and 138 µg/g DDE. Phenolic metabolites of PCBs and DDE have also been identified in field-collected seal excreta (Jansson et al. 1975; Sundstrom et al. 1975).

High levels of PCBs (>100 µg/g in blubber) have been linked to premature parturition in sea lions (DeLong et al. 1973) and reproductive failure in seals from the Baltic (Helle et al. 1976b) and the Dutch Wadden Sea (Duinker et al. 1979) but the cause and effect relationships are not well established. Helle et al. (1976b) analysed 109 female seals (mainly ringed seals) of reproductive age from the Baltic area and found a high frequency of pathological changes in the uterus which explained the low rate of reproduction. They also found that ΣDDT and PCB concentrations were significantly higher in the group showing pathological changes than in those which did not show such changes. On reviewing the results of Helle et al. (1976b) (index no. 251), Holden (1978a) noted that the differences in residue levels between non-pregnant and pregnant females seemed insufficient to explain the observed failure to reproduce. Nonpregnant females can be expected to have higher organochlorine levels since loss of residues via lactation does not occur. The finding of PCDFs in Baltic seal blubber including the toxic TCDF isomer and further monitoring in other seal populations may help explain the connection between organochlorine levels and reproductive failure. PCDFs and PCDDs are known to have a depressive effect on reproductive capacity in mammals, and on the viability of offspring of exposed mothers (McConnell 1980). A survey of PCDFs and PCDDs in seal populations would be useful to determine ratios of these micro contaminants with PCBs and to identify populations having high PCDF and PCDD exposure.

CONCLUDING REMARKS

We have attempted to extract some concentration norms for toxicant burdens in marine mammals from the existing data base. Only for mercury and chlorinated hydrocarbons in pinnipeds were the data numerous enough to approach

this goal. But even there, the available data were sufficiently unsystematic from a geographic and chronological point of view to preclude the certain delineation of the various factors separately, i.e. geographic location, date of sampling, and age of animals. Statistically, the size of samples (consisting frequently of only 1-5 animals) was more often than not too small, and this should be remedied in future data gatherings. Vital information such as the sex and age of animals, as well as the standard deviation of the set of data comprising the sample, was frequently lacking. Such data do not lend themselves well to statistical treatment. The aging of whales, particularly narwhals and belugas, is a problem that should be addressed in view of the connection between age and toxicant burden. The data base for toxicant burdens in cetaceans is presently too small to allow the extraction of concentration norms for these animals. In view of the rapidly increasing development of hitherto pristine areas, and the anticipated banning in the future of the killing of a number of whale species, the gathering of such data is pressing.

Aside from the difficulties mentioned, there is a further limitation imposed by the nature of the data; namely, that "total" heavy metal concentrations are by themselves insufficient to assess either the health status of the animals, or the effective toxicity of the toxicant in question. Yet, these "total substance" concentrations are important and necessary as they are the only direct indicator of the actual burden that an animal carries. Without such "total" concentrations any other metal species concentration datum is by itself incomplete and insufficient. Total concentrations can provide a much needed benchmark for what is to be regarded as a "normal" or an "abnormal" heavy metal burden for animals in the wild. The interpretation of such burdens in terms of the well-being of the animal must, of course, be sought through other types of data.

The available data base for marine mammals is almost devoid of any reference to antagonistic or synergistic effects of metals other than mercury and selenium. Only in two studies to date (Honda et al. 1983; Wagemann et al. 1983) have elements other than these two also been measured, and interrelationships shown to exist. Whether these relationships are of such generality as to be found in all cetaceans is still an open question.

The data base for organochlorine residues consists mainly of ΣDDT and PCB results. DDT use has been largely eliminated and many past uses of PCB's curtailed during the 1970's in many regions adjacent to marine mammal habitats in northern waters. Future analysis will hopefully focus on other organochlorines in wide use until recently, such as chlordane, HCH, toxaphene as well as PCDD's and PCDF's. Further work on the phenolic and methylsulfone metabolites of PCB's, DDT and other chlorinated aromatics would also be useful since this may provide an insight into rates of elimination of these contaminants, and estimates of total body burdens of each compound.

ACKNOWLEDGMENTS

We sincerely thank the persons who helped in preparing this manuscript: Messrs. A. Lutz, J. Solomon, R. Hunt, and K.C. Tam for analytical work; Ms. S. Elliott and Mr. J. Maniar for computer work and calculations; Miss R. Blosmanis for initial tabulations of data and Mr. K.E. Marshall for computer searches of data bases; Mrs. G. Decterow and Miss M. Ziprick for typing the manuscript and Mrs. L. Fletcher for final production by word-processor; Mr. A. Blouw for graphical work.

We also wish to thank our colleagues Messrs. B. Fallis, A. Lutz, and F.A.J. Armstrong for providing some unpublished metal concentration data, Dr. T.G. Smith for providing us with some seal samples from the Antarctic, and Mr. P. Richard for assistance with the translation of the Abstract.

* - Different tissues belong to the same animal or groups of animals which have the same Index No.

\+ - Dorsal meat

† - S.D. estimated from the range

A - Gravid

B - Non-gravid

c - S.D. from repeated analysis of the same sample

∿ - Approximately

T - Blue-White and Striped Dolphins are used interchangeably, depending on the name used in the original literature.

* - Different tissues belong to the same animal or groups of animals which have the same Index No.

[+] - Dorsal meat

† - S.D. estimated from the range

∿ - Approximately

■ - Concentrations are age correlated; significant at 1.0%

α - Concentrations are age correlated; significant at 0.1%

β - Arithmetic mean of three determinations per sample

γ - Kept in captivity for one year

A - Gravid

* - Different tissues belong to the same animal or groups of animals which contain the same Index No.

\+ - Dorsal meat

† - S.D. estimated from the range

② - No. of animals not given. See Gaskin et al. (1983). Index No. 92A and B.

~ - Approximate sampling date or several years previously.

T - Blue-White and Striped Dolphins are used interchangeably, depending on the name used in the original literature.

* - Different tissues belong to the same animal or groups of animals which have the same Index No.

\+ - Dorsal meat

† - Standard deviation calculated from the range

∿ - Approximate sampling date or several years previously.

T - Blue-White and Striped Dolphins are used interchangeably, depending on the name used in the original literature.

Table 13. Reference concentrations of ΣDDT (wet weight basis) in different tissues of Pinnipeds.

* - Different tissues belong to the same animal or groups of animals which have the same Index No.

♦ - Dorsal meat

† - Standard deviation calculated from the range.

∿ - Approximate sampling date or several years previously.

ε - Total DDT + PCB

δ - as DDE

A - Gravid

B - Non-gravid

* - Different tissues belong to the same animal or groups of animals which have the same Index No.

* - Dorsal meat

± - S.D. estimated from the range.

~ - Approximate sampling time or several years previously.

Σ - Total DDT + PCB

A - Gravid

B - Non-gravid

APPENDIX

Statistical Treatment

Scheffé's multiple comparison of means method is based on the formula:

$$(\overline{Y}_i - \overline{Y}_{i+x}) = \pm S[MSE(1/n_i + 1/n_{i+x})]^{1/2}$$

where "i" is the running index for the k groups (means) being compared, and x is an incremental integer from 1 - k-1.

$$S = [(k - 1) F_{k-1,n-k,1-\alpha}]^{1/2} \text{ , and}$$

$$MSE = \frac{\sum_{i=1}^{k} \sum_{j=1}^{ni} Y_{ij}^2 - \sum_{i=1}^{k} n_i(\overline{Y}_i)^2}{(n - k)}$$

where "j" is the running index within a group, and "Y_{ij}" is an individual observation. When the interval (1st eq.) does not contain zero, the null hypothesis H_o: $u_i = u_{i+x}$ is rejected.

Individual observations "Y_{ij}" were not available. However, MSE can be expressed in terms of the k estimates of individual variances S_1^2, S_2^2, ... S_k^2 namely,

$$MSE = \frac{[(n_1-1)S_1^2 + (n_2-1)S_2^2 + \ldots + (n_k-1)S_k^2]}{(n_1 + n_2 + n_3 + \ldots\ldots + n_k-k)}$$

which was the formula used to obtain MSE from the given standard deviations. If the standard deviations were not given but the range (w) and number of samples (n) were, the standard deviation was estimated from f(w), where "f" is a multiplication factor appropriate for the given number of samples, and obtainable from statistical handbooks, e.g. Beyer (1966) p. 271.
